² Polymer Composites Laboratory, Department of Metallurgy, Indian Institute of Science, Bangalore-560012, India

ABSTRACT: This is the first report concerning the use of vinyl polyperoxide, namely, poly(methyl methacrylate) peroxide (PMMAP), as a thermal initiator for the synthesis of active polymer PMMAP-PS-PMMAP by free-radical polymerization with styrene. The polymerizations have been carried out at different concentrations of macroinitiator PMMAP. The active polymers have been characterized by ¹H NMR, DSC, thermogravimetric analysis, and gel permeation chromatography. PMMAP-PS-PMMAP is further used as the thermal macroinitiator for the preparation of another block copolymer, PMMA-b-PS-b-PMMA, by reacting the active polymers with methyl methacrylate. The block copolymers have been synthesized by varying the concentrations of the active polymers. The mechanism of block copolymers has been discussed, which is also supported by thermochemical calculations. Studies on the surface texture and morphology of the block copolymer of polystyrene (PS) and PMMA material have been carried out using scanning electron microscopy. Furthermore, in this article, a blend of the same constituent materials (PS and PMMA) in proportions (v/v) similar to that contained in block copolymers has been formulated, and the morphology and surface textures of these materials were also investigated. A comparative microscopical evaluation between two processing methods was done for a better understanding of the processing route dependence of the microstructures. © 2001 John Wiley & Sons, Inc. *J Polym Sci A: Polym Chem* 39: 546–554, 2001

Keywords: macroinitiator; active polymer; block copolymer; morphological characterization

INTRODUCTION

Polymer alloys and blends are gaining the increasing attention of research workers as they can be

suitably processed to yield tailor-made properties to meet the stringent demands in technologically advanced applications.¹ Recently, there is a growing interest in the usage of block copolymers in varied fields like polymer alloys (blends), modifications, compatibility improvements, and surface modifications, to name a few.^{2–5} Furthermore, the surface texture and morphological features of these block copolymers and blends have attracted the attention

of microscopists because this approach clearly provides an idea about the physical arrangement of different constituents present in the materials.^{6–13}

Unlike simple low molecular weight peroxides, their polymeric counterparts, although long known, have not been studied extensively with respect to their initiating characteristics.^{14,15} Among polymeric peroxides, vinyl polyperoxides¹⁵ play a primary role because they are obtained via radical, alternating copolymerization reactions of vinyl monomers and oxygen. Vinyl polyperoxides are attractive candidates owing to their divergent characteristics of exothermic degradation,^{16–18} autopyrolysis,¹⁹ special fuels,^{19,20} autoacceleration,²¹ curatives in coating and molding applications,²² and finally their use as base-assisted initiators.²³ Vinyl polyperoxides are superior to acid polyperoxides^{24–26} on the basis of their high solubility in vinyl monomers, safety in handling, economy, and simplicity of synthesis.

This is the first report on the use of poly(methyl methacrylate) peroxide (PMMAP) as a thermal initiator for the polymerization of styrene resulting in the synthesis of active polymers. The metamorphosis of a block-into-block copolymer has been carried out since this aspect appears to be quite interesting and less explored.^{27,28} To widen the scope of the present investigation, an attempt has been made to study and then characterize the morphological features of the constituent materials first and thereafter examine the surface texture of the block copolymer using scanning electron microscopy (SEM). To make the microscopy part of the work more comprehensive, blends of the same constituent phases in proportions (v/v) similar to those seen in block copolymers were made, and the texture and morphological features of these blends were also studied. Based on these efforts, a comparative evaluation has been attempted in this article. A preliminary investigation to correlate processing-route-dependence of the microstructure in these polymeric systems has also been initiated.

EXPERIMENTAL SECTION

Materials

Methyl methacrylate (MMA) and styrene (STY) were purified from the inhibitor by washing with 10% NaOH solution and then with water several times. After drying over anhydrous Na₂SO₄, MMA and STY were distilled under reduced pres-

sure. The Cobalt(II) tetraphenylporphyrin [Co(II)TPP] (Aldrich) was used as received. Methanol, petroleum ether, chloroform, cyclohexane, acetonitrile, ethyl acetate, benzene, chlorobenzene, and pyridine (Py) were purified by adopting established procedures.²⁹

Preparation of Co(II)TPP(Py) Complex

Co(II)TPP(Py) complex was prepared by mixing solution of equivalent concentrations (1.0×10^{-4} mol/L) of Co(II)TPP and Py, respectively, in MMA. The formation of Co(II)TPP(Py) has been confirmed by the bathochromic shift of 413 (soret band) and 528 nm (Q band) of Co(II)TPP complex to 440 and 553 nm, respectively, in the UV-vis absorption spectra.

Synthesis of PMMAP

Co(II)TPP(Py) (1.0×10^{-4} mol · L⁻¹) in MMA (8.4 mol · L⁻¹) solution was placed in a 300-mL Parr reactor (Parr Instrument Co.) and pressurized at 200 psi of oxygen pressure. The polymerization was carried out at 50 °C with constant stirring for 8 h, and the polyperoxide was precipitated from the reaction mixture using petroleum ether as a nonsolvent. Thus, the PMMAP obtained was purified by repeated precipitation from chloroform solution and dried in vacuum to a constant weight.

Synthesis of PMMAP-PS-PMMAP “Active” Polymer

The preparation of polystyrene (PS) involved the use of macroinitiators PMMAP and STY at 70 °C for 3 h in Pyrex ampoules, which were previously sealed after repeated freeze-thaw cycles in liquid nitrogen. The polymerizations were carried out at various concentrations of PMMAP. Following this, the active polymers PMMAP-PS-PMMAP were precipitated using methanol as a nonsolvent, purified by repeated precipitation from chloroform solution, and dried in vacuum to a constant weight. The PMMAP that remained was removed by precipitating the polymers twice in petroleum ether/ethyl acetate (1 : 1) followed by methanol. The active polymer PMMAP-PS-PMMAP containing peroxide units in the main chain was collected.

Synthesis of Poly(methyl methacrylate)-Block-Polystyrene-Block-Poly(methyl methacrylate)

The PMMAP-PS-PMMAP active polymer as well as MMA were taken in a Pyrex ampoule, which

was previously sealed after repeated freeze-thaw cycles in liquid nitrogen, and thermostated³⁰ at 75 °C for 5 h. The polymerizations were carried out at various concentrations of active polymers. The polymer, poly(methyl methacrylate)-block-polystyrene-block-poly(methyl methacrylate) (PMMA-*b*-PS-*b*-PMMA), obtained was precipitated over methanol and purified by repeated precipitation from chloroform solution and dried at 50 °C in vacuum to a constant weight.

Purification of PMMA-*b*-PS-*b*-PMMA

The STY and MMA homopolymers, made as by-products in the preparations of PMMA-*b*-PS-*b*-PMMA, were purified by solvent extractions. About 2 g of polymer product were extracted with cyclohexane for 50 h by a Soxhlet extractor to extract PS using cylindrical filter paper. The dried residue was treated with acetonitrile for 50 h to extract PMMA. The remaining polymer was extracted with benzene for 50 h to extract PMMA-*b*-PS-*b*-PMMA. Each extracted solution was concentrated by evaporating the excess solvent using a rotary evaporator (Yamato Hi Tec, Model RE-51), and they were added to 300 mL of methanol to precipitate out each polymer.

Synthesis of PS and PMMA Blend

The blend was prepared by dissolving 75 : 25 (v/v) of PMMA and PS constituents, respectively, in CHCl₃ followed by precipitation with methanol^{31,32} and dried under vacuum to a constant weight.

Analytical Techniques

A Bruker ACF 200-MHz model spectrometer was used to record the ¹H NMR spectra using CDCl₃ as a solvent. The chemical shifts were assigned with reference to tetramethylsilane. Thermal analysis was done on a Perkin-Elmer DSC-2C at a heating rate of 10 °C/min under nitrogen atmosphere. Thermogravimetric analysis (TGA) was carried out on a Perkin-Elmer TGS-2 instrument under nitrogen atmosphere at a heating rate of 10 °C/min. The number average molecular weights ($\bar{M}_n$) and weight average molecular weights ($\bar{M}_w$) and polydispersity index ($\bar{M}_w/\bar{M}_n$) were estimated using gel permeation chromatography (GPC). GPC was performed on a modular system comprising of a Waters 590 high-performance liquid chromatography pump, a Waters 717 autosam-

pler (Waters Corp., Milford, MA), and an ERMA ERC-7515A refractive index detector (ERMA CR, Inc., Tokyo). The column used was a 60-cm PLGel mixed-B 10- μ m column (Polymer Laboratories Ltd., Shropshire, UK). The mobile phase used was unstabilized tetrahydrofuran (EM Science, Gibbstown, NJ) at a flow rate of 0.95 mL/min. The molecular weights were calculated using 13 narrow PS standards from 6,300,000 to 580 (Pressure Chemical Co., Pittsburgh, PA). The software used for the calculations was Polymer Laboratories Ltd. caliber version 7.04 (Polymer Laboratories Ltd.).

SEM Microscopy

The samples processed, using the routes highlighted earlier, were sputter-coated for about 20 min to ensure the deposition of a conducting layer employing a gold target in a JEOL-make unit. The samples were then mounted on a stub that could be inserted through the specimen holder assembly into the chamber of the microscope for viewing at an operating voltage of 20 kV. A JEOL-make (JSM 840A) SEM microscope helped first in the characterization of the surface topography and then in the morphological features of the prepared samples. In characterizing these, the experiences gained while studying the homopolymers³⁰ were helpful.

Previous effort³⁰ concentrated more on homopolymer and block copolymer microscopy than on the present stresses on the comparative situation prevailing in blend and block copolymers, an aspect not reported in the literature using the visual methods. The changes in the surface details along the specimen cross section, if any, were carefully examined, and repetitive features of relevance were photographed. The procedure was also repeated for the case of blended systems. For the ensuing proper interpretation of the scanning micrographs, an exercise of identifying the morphological and surface texture features when only one (homo) phase system is present was undertaken by preparing samples that have either PMMA or PS only as an end product. The physical features of both the block copolymer and the blends were then interpreted with this as a standard reference.

RESULTS AND DISCUSSION

Characterization and Molecular Weight of PMMAP

As far as the ¹H NMR spectrum for PMMAP is concerned, it showed resonance signals at 1.44,

Figure 1. ^1H NMR spectrum of PMMAP-PS-PMMA.

3.76, and 4.34 ppm, which were assigned to $\alpha\text{—CH}_3$, —OCH_3 , and —OCH_2 protons, respectively.²⁶ The $\bar{M}_n$ and $\bar{M}_w/\bar{M}_n$ values of PMMAP were 3150 and 1.7, respectively. It should also be noted that the $\bar{M}_n$ value is high, and the $\bar{M}_w/\bar{M}_n$ values are low using the present method compared to 2,2'-azobis(isobutyronitrile) (AIBN)-initiated polymerization.¹⁵

Characterization and Molecular Weight of PMMAP-PS-PMMA “Active” Polymer

The ^1H NMR spectrum of PMMAP-PS-PMMA active polymer is displayed in Figure 1. The peaks at 1.44, 3.76, and 4.34 ppm correspond to the $\alpha\text{—CH}_3$, —OCH_3 , and —OCH_2 protons, respectively, of PMMAP segments;³³ on the other hand, those at 1.42, 1.84, and 6.4–7.5 ppm refer to methylene, methine, and aromatic protons of the PS block,³⁴ respectively. It may be noted that α -methyl and methylene signals at 1.44 and 1.42 ppm of the PMMAP segments and PS block merge into a single peak around 1.4–1.5 ppm.

The results derived for bulk polymerization of STY using the macroinitiator PMMAP are presented in Table I. From the tabulated data, it can be seen that the yield (%) and $\bar{M}_w/\bar{M}_n$ of the active polymer increase with an increase in concentration of PMMAP. The broader polydispersity can be attributed to the chain-transfer reaction asso-

Figure 2. DSC thermogram of PMMAP-PS-PMMA.

ciated with the degradation products of PMMAP, which in the present experimental condition are formaldehyde and methyl pyruvate,^{33,35} respectively. Of these products, formaldehyde is the chain-transfer agent.³⁰

Thermal Analysis of PMMAP-PS-PMMA “Active” Polymer

The DSC and TGA traces of PMMAP-PS-PMMA active polymer are depicted in Figures 2 and 3. The exotherm observed around 140 °C as well as the broad endotherm observed around 400 °C (Fig. 2) are ascribed to the decomposition of the PMMAP segments³⁵ and PS block,³⁶ respectively. The TGA traces (Fig. 3) of this active polymer yield two-step degradation, the first step of which has a small weight loss around 140 °C, followed by a second step where a major loss is registered around 400 °C. These weight losses are attributed to the PMMAP segments and PS block, respectively.

In reference to the position of the peroxy segments in the PS backbone, the PMMAP-PS-PMMA active polymers were decomposed at 120 °C for 15 h in chlorobenzene, following which the $\bar{M}_n$

values were calculated. These values are listed in Table I; from the data, it appears that the peroxy segments (i.e., PMMAP segments) are posited in the chain ends of PS, or otherwise a significant reduction in the molecular weight would have been observed.

Mechanism of PMMAP-PS-PMMA "Active" Polymer

The occurrence of the PMMAP segments in PS (Fig. 1) can be viewed as a suggestion that PMMAP macroradical, that is, δ -peroxy alkoxy radical, formed by the random homolysis of the peroxide linkage, is responsible for the initiation of STY polymerization. The propagating radicals of PS, however, undergo bimolecular termination by radical recombination with the PMMAP seg-

ments to yield the PMMAP-PS-PMMA active polymer.

Metamorphosis of Block-into-Block Copolymers

While it is recognized that block copolymers may be synthesized using free radicals,³⁷ that for the metamorphosis of a block copolymer macroinitiator like PMMAP-PS-PMMA into another block copolymer like PMMA-*b*-PS-*b*-PMMA is an area that is quite interesting and less explored.^{27,28} By using PMMAP-PS-PMMA as a thermal initiator, PS was converted into another block copolymer like PMMA-*b*-PS-*b*-PMMA by the degradation of peroxide segments in the presence of monomer MMA. The results for the block copolymerization of MMA using active polymer PMMAP-PS-PMMA are recorded in Table II. From this tabulation it appears that PMMA-*b*-PS-*b*-PMMA show narrow polydispersity compared to the active polymer PMMAP-PS-PMMA. This observation points out the concentration of degradation products is very small, owing to the presence of less proportion of peroxy segments in the chain ends. Consequently, chain-transfer reactions are drastically reduced, owing to the decrease in polydispersity.

¹H NMR Spectrum of PMMA-*b*-PS-*b*-PMMA

Reconfirming the spectra results reported earlier,³⁰ the ¹H NMR spectrum of the present system showed the characteristic signals of PS as 1.4 (—CH₂—), 1.84 (>CH—), 6.4–6.6 (*o*-protons), and 7.2 ppm (*p*- and *m*-protons); and of PMMA as 0.8–1.1 (—CH₃), 1.89 (—CH₂—), and 3.65 ppm (—OCH₃), thereby confirming the formation of PMMA-*b*-PS-*b*-PMMA. The absence of characteristic PMMAP signals in the ¹H NMR spectrum of PMMA-*b*-PS-*b*-PMMA shows the lack of any residual PMMAP segments in the backbone (Fig. 4). Furthermore, from the peak integration ratio of —CH₂ protons of PS and PMMA blocks, it can be

uent phase systems (i.e., PMMA and PS). As stated in the experimental section, the interpretation of the features was facilitated by compiling extensive SEM databases when only one phase system (PMMA or PS) is present and then comparing the scanning micrograph obtained on the products of the differently processed routes with the developed database. This exercise with monophase systems showed that for the case when only PS is present, the photographs yielded an irregular contour, undulating terrain-bearing surface that had porous sites on them as well as evidence of sprinkling of particles.³⁰ The PMMA system, on the other hand, yielded a smooth near-constant cross-sectional area bearing threadlike features that show an occasional twist or curl or U-bend.³⁰

Considering the case of the blended category first, a lower magnification view, where PMMA, having a smooth surface and sandwiched between PS bearing materials, marked by letter S can be seen in Figure 5(a). Also visible are the two interface regions forming the boundary between the PS and PMMA (the latter marked by letter M) regions. A feature noticed in this blend is that PS has a rough surface with a contour showing many protrusions [as, for instance, at P in Fig. 5(b)]. Further, in the same photograph [Fig. 5(b)] the rough terrain exhibited by the surface of the PS bearing region (for instance, at regions marked by letter T) is very distinct.

As a result, it may be said that the blend has a smoother PMMA, containing regions of PS adjacent to it and where the PS has either the appearance of a surface distributed with dispersed particles or what can be categorized as porous, rough texture. Also, the fact that a distinct interphase interface region can be seen between the PS- and PMMA-juxtaposed regions emerges from the present article. Having examined the blends, the features seen in the block copolymer case are now considered.

Thus, the features, wherein the block copolymer displays a bend at a region marked K [following which the surface of the material shows rough protruded and cross-sectional-wise expanded features (at S)] typically seen in the PS regions, are shown in Figure 6(a). (FIG6) Figure 6(a) also shows smooth PMMA (marked P on the left side) leading to a region where rough-surface-bearing PS (marked S) exists. This feature of PMMA leading to a differently appearing morphological material is best seen in Figure 6(b),³⁰ where at the region marked M' a trident-shaped PMMA

Figure 5. (a). The rough surface feature of PS-bearing regions posited on either side of a smooth surface bearing PMMA. (b). The surface feature of a PS showing very uneven terrain as well as the edge displaying protrusions.

emerges. One branch of this trident (the top marked M') leads to a broadened and expanded region whose surface appears to be irregular (marked S'). The central thick branch marked M'' also leads to a wider region marked S''. The third branch at the lower wing marked M''' leads to a region where at the point marked K a well-formed, irregular, porous and rough-terrain-bearing PS region marked S''' may be seen.

As a result, it is of interest to note that the PS component of the micrograph displayed a typically rough irregular surface similar to what was seen in the case of the blended material. The distinction between the two differently processed but bearing the same volume fractions of polymer materials surfaces when the PS part of the block copolymer case has been considered. Here, the PS

Figure 6. (a). SEM micrograph showing both PMMA and PS bearing regions in block copolymer. (b). Scanning micrograph depicting the branching segments of PMMA and leading to PS containing regions. The photograph also displays the distribution of PS along with PMMA.

segment is continuous with PMMA. Furthermore, the porous nature of the surface on PS, seen earlier with the blended portion, is conspicuous by its poor presence in the scanning micrograph for the block copolymer case. In addition to these, whereas in blends the interface between the PS and PMMA regions are distinct, a similar feature is difficult to see in the block copolymer. Thus, a distinct difference both in the surface texture and distribution of the porous sites in PS occurs for the blends together with a block copolymer. Also, whereas a distinguishable interface between the two polymeric materials exists for the former, the same is not the case, expectedly, for the latter. The results re-emphasize the well-known fact that the processing route contributes in a signif-

icant way to the appearance of the structure as seen in SEM.

CONCLUSION

The thermal-initiating potentialities of PMMAP for the synthesis of active polymer PMMAP-PS-PMMAP have been demonstrated. The efficiency of the active polymer has been measured by the synthesis of block copolymer PMMA-*b*-PS-*b*-PMMA. Also, noticeable differences in the surface texture and morphology of the block copolymer together with the blend case exist. Thus, the blended material showed a distinguishable interfacial region between two homopolymers, and the PS material that displayed a rough surface with a contour showing many protrusions for the block copolymer case yielded two homopolymers that are continuous and without a well-demarcated interface region. Further, the surface roughness exhibited for the PS part of the block copolymer is much less prominently seen.

In summary, vinyl polyperoxides are potentially inexpensive materials because they can be made by reacting a vinyl monomer with air. Also, their synthesis is simple and handling is less hazardous compared to acid polyperoxides. All of these considerations suggest that vinyl polyperoxides can be used as initiators.
