

## **MECHANICAL TESTS OF SOME MYSORE TIMBERS**

*By John H. C. Kann, B.Sc. (Lond.)*

The tests of which the results are here given were carried out on specimens of timber kindly provided for the purpose by the Chief Conservator of Forests in Mysore.

The timber was received in the form of logs about four feet long ; these were quartered and stored in a dry situation with free access of air for at least a year before use.

When the test-specimens had been cut to shape and size, they were kept for several days—sometimes weeks—in a dry room and then measured accurately by micrometer before test. The actual details of measurements have not been given, but each measurement shown in the paper is the mean of at least three readings of the micrometer. On account of the length of exposure to the atmosphere, all specimens when measured and tested must have been air-dry ; so, although no moisture determinations were made, it is probable that the moisture content of the specimens varied between  $5\frac{1}{2}$  and 11 per cent. according to the humidity of the atmosphere.

The tests were performed on a 10,000-lb. Denison's Single Lever Testing Machine (hand-operated) in which the load is applied by traversing a sliding weight along the horizontal lever or steelyard, and the strain is taken up by means of a screw. Loads are read direct in pounds on a scale engraved on the steelyard ; the scale reads up to 10,000 lbs., but the sliding weight can be moved to a position corresponding to a total load of 10,170 lbs. When specimens failed to break down under a load of 10,170 lbs., additional load was in a few cases applied by means of cast iron bars suspended in a stirrup at a point near the end of the lever ; this procedure was adopted in a few cases only, as its continued application was considered likely to damage the knife-edges.

A dead-weight calibration of the machine showed a constant error of about 0·3 per cent. up to 1,000 lbs. ; an error of 0·3 per cent. in readings having such large variations as are met with in all mechanical tests on timber is so small as to be absolutely negligible.

The following tests were carried out :—(I) Transverse, (II) Tension, (III) Single Shear, and (IV) Compression ; in addition to these, density determinations were also made.

I. *Transverse Tests.*—These were performed on specimens approximately 1" wide, 2" deep and 36" span between knife-edges. In order to prevent cutting, small plates of sheet iron were interposed between the knife-edges and the specimens.

Assuming the ordinary elastic theory to hold good, the application of a load  $W$  lbs. at the centre of a span of  $l$  inches will cause a maximum stress  $f = \frac{Wlh}{8I}$ , where  $h$  is the depth of the section in inches and  $I$  the second moment in inch units. On the same assumption, the deflection of the beam at the centre will be  $\Delta = \frac{Wl^3}{48E}$ ,  $E$  being Young's Modulus.

Let  $b$  be the breadth of the section.

$$\text{Then } I = \frac{bh^3}{12}$$

Substituting for  $l$  its value, 36, and for  $I$  its value,  $\frac{bh^3}{12}$ , we get

$$f = \frac{54W}{bh^2} \text{ and } E = \frac{11664W}{bh^3 \Delta}$$

If we now substitute 1 for  $b$  and 2 for  $h$ , we get

$$f_0 = 13.5 W \text{ and } E_0 = \frac{1458 W}{\Delta}$$

Let the actual values of  $b$  and  $h$  be  $1 + \delta b$  and  $2 + \delta h$ .

Then the actual values of  $f$  and  $E$  will be

$$f = f_0 + \delta f = f_0 + \frac{df}{db} \delta b + \frac{df}{dh} \delta h$$

$$\text{and } E = E_0 + \delta E = E_0 + \frac{dE}{db} \delta b + \frac{dE}{dh} \delta h.$$

$$\text{Now } f = \frac{54W}{bh^2} \therefore \frac{df}{db} = - \frac{54W}{b^2h^2} = - \frac{f}{b}$$

$$\text{and } \frac{df}{dh} = - \frac{2 \times 54W}{bh^3} = - \frac{2f}{h}$$

$$\therefore f = f_0 + f \frac{\delta b}{b} - \frac{2f \delta h}{h}$$

As the actual values of  $b$  and  $h$  did not vary much from one and two inches respectively, we can put

$$\begin{aligned} f &= f_0 \left( 1 - \frac{\delta b}{1} - \frac{2 \delta h}{2} \right) \\ &= f_0 (1 - \delta b - \delta h) \quad \therefore f = 13.5 \text{ W} (1 - \delta b - \delta h). \end{aligned}$$

Similarly,  $E = \frac{11664 \text{ W}}{bh^3 \Delta}$

$$\frac{dE}{db} = -\frac{11664 \text{ W}}{b^2 h^3 \Delta} = -\frac{E}{b}$$

$$\text{and } \frac{dE}{dh} = -\frac{3 \times 11664 \text{ W}}{bh^4 \Delta} = -\frac{3E}{h}$$

$$\therefore E = E_0 - E \frac{\delta b}{b} - \frac{3E\delta h}{h}$$

$$= E_0 \left( 1 - \frac{\delta b}{1} - \frac{3\delta h}{2} \right)$$

$$E = 1458 \text{ W} \left( 1 - \delta b - \frac{3}{2} \delta h \right)$$

In working out the results of the Transverse Tests, the two formulae derived above for  $f$  and  $E$  were applied in all calculations of Fibre-Stress, Modulus of Rupture and Young's Modulus ; in the two former cases the values of  $\delta b$  and  $\delta h$  were taken from the dimensions of the central cross-section, and in the latter case they were taken from the dimensions of the average cross-section.

**II. Tensile Tests.**—The specimens used for the Tensile Tests, shown in Fig. 1, were of rectangular cross-section,  $\frac{1}{2}$ " thick through-

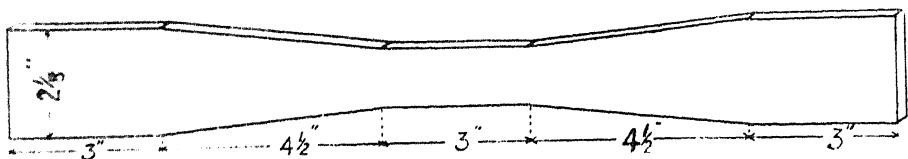

FIG. 1. TENSILE TEST SPECIMEN.

out, and 18" long ; the maximum width of section, for 3" at each end, was  $2\frac{1}{8}$ " ; the width was then tapered gradually towards the centre for a distance of  $4\frac{1}{2}$ " at each end, thus leaving a parallel portion for a distance of 3" at the centre of the specimen ; to this central portion of minimum cross-section I shall refer as the contracted portion.

The specimens were initially made  $1\frac{1}{2}$ " wide in the contracted portion, so as to have a cross-sectional area of  $\frac{3}{4}$  square inch; but in some cases this had to be reduced as the limiting load of 10,170 lbs. was insufficient to cause fracture, and in other cases further specimens had to be prepared with reduced width in the contracted portion owing to the original specimens fracturing at the enlarged ends due to the crushing-effect of the wedges by which they were held in the shackles.

In spite of all precautions, which ensured that the fractures all took place in the contracted portion, the variations in breaking-stress for any one species were very wide, the maximum being in some cases as much as three times the minimum. On the whole, however, the average breaking-stress works out — as would be expected — at rather less than the Modulus of Rupture. The results are shown in Schedule II.

**III. Shear Tests.**—The results of the Shear Tests are also given in Schedule II.

The specimens were prepared as follows:—

Rectangular blocks were cut, 7" long,  $2\frac{1}{2}$ " wide and 1" thick; a rectangular block 3" long,  $2\frac{1}{2}$ " wide and  $\frac{1}{2}$ " thick was cut away from the centre of one side, leaving a specimen  $\frac{1}{2}$ " thick in the centre with ends 1" thick for a length of 2". The specimen is shown in Fig. 2. These

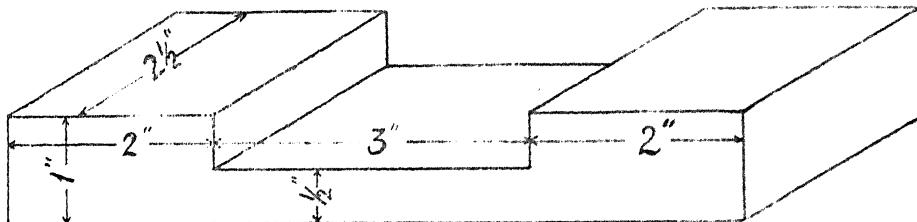

FIG. 2. SINGLE SHEAR TEST SPECIMEN.

specimens were placed in specially prepared shackles by means of which the ends were pulled apart from one another, thus tending to shear them through a central plane—a continuation of the boundary surface of the hollow cut in the middle portion of the specimen; the area in shear, if the specimens could have been prepared accurately to size, would, therefore, be  $2\frac{1}{2}$ " (width)  $\times$  2" (length), i.e. 5 square inches at each end. The shackles were so constructed that the axis of pull lay in the plane of the shear. On account of unavoidable inaccuracy in the preparation of the specimens, it was necessary to take measurements of the area in shear at each end of the specimen; in many instances the shear occurred in the larger of the two sections in shear—due to local variations in strength; but only the dimensions at the end where the specimen sheared are shown in the Schedule.

**IV. Compression Tests and Density Determinations.**—The specimens initially used were  $1\frac{1}{4}$ " cubes and rectangular blocks  $1\frac{1}{4}$ " square in cross-section and  $2\frac{1}{2}$ " long. In some cases the strength of these specimens was too great for the capacity of the machine and the machine was overloaded, as mentioned on page 1 : in other similar cases, the specimens were cut down to 1" cubes and blocks  $2'' \times 1'' \times 1''$ .

Prior to testing the specimens were accurately measured and weighed on a chemical balance ; the figures thus obtained formed the basis of the density determinations, which are shown together with the Compression Tests in Schedule II.

The average results for the various logs dealt with in Schedules I and II have been collected together and shown in Schedule III ; in this Schedule, in order to reduce the number of figures, stresses have been shown only in tons per square inch.

It will be observed that two logs of *Albizzia odoratissima* were tested ; the first mentioned was sent from Lakkavalli Range, the second from Kankankote Range, both logs being taken from the middle of the trunk. Three logs of *Terminalia paniculata* were supplied ; the first was from the middle of the trunk, the other two from the upper trunk.

It should, perhaps, be mentioned that for the Transverse Tests the specimens were cut with their depth radial to the annual rings of the timber and the same was the case for the Shear Tests, that is, the shear was in a radial plane. The specimens for tensile and compressive tests were so cut that the direction of pull or thrust coincided with the axis of the tree and not necessarily with the direction of the grain, which was in some cases very far from being straight.
