Points-to Analysis as a System of Linear Equations

Rupesh Nasre, R. Govindarajan

Indian Institute of Science, Bangalore

Abstract. The efficiency of a points-to analysis is critical for several compiler optimizations and transformations, and has attracted considerable research attention. Despite several advances, the trade-off between precision and scalability still remains a key issue. In this work, we propose a novel formulation of the points-to analysis as a system of linear equations. With this, the efficiency of the points-to analysis can be significantly improved by leveraging the advances in solution procedures for solving the systems of linear equations. We demonstrate that the proposed transformation is non-trivial and becomes challenging due to the following facts, namely, multiple pointer indirections, address-of operators and multiple assignments to the same variable. The problem is exacerbated by the need to keep the transformed equations linear. Despite this, we successfully model all the pointer operations. The main technical contribution of our work is a novel inclusion based context-sensitive points-to analysis algorithm based on prime factorization. Experimental evaluation on SPEC 2000 benchmarks and two large open source programs reveals that our approach is competitive to the state-of-the-art algorithms. With an average memory requirement of mere 21MB, our context-sensitive points-to analysis algorithm analyzes each benchmark in 55 seconds on an average.

1 Introduction

Points-to analysis enables several compiler optimizations and remains an important static analysis technique. With the advent of multi-core hardware and parallel computing, points-to analysis enjoys enormous importance as a key technique in code parallelization. Enormous growth of code bases in proprietary and open source software systems demands scalability of static analyses over billions of lines of code. Several points-to analysis algorithms have been proposed in literature that make this research area rich in content[1, 28, 5, 2, 31, 17, 23].

A points-to analysis is a method of statically determining whether two pointers may point to the same location at runtime. The two pointers are then said to be aliases of each other. For analyzing a general purpose C program, it is sufficient to consider all pointer statements of the following forms: address-of assignment ($\mathtt{p} = \&\mathtt{q}$), copy assignment ($\mathtt{p} = \mathtt{q}$), load assignment ($\mathtt{p} = *\mathtt{q}$) and store assignment ($*\mathtt{p} = \mathtt{q}$) [25].

A flow-insensitive analysis ignores the control flow in the program and, in turn, assumes that the statements could be executed in any order. A context-sensitive analysis takes into consideration the calling context of a statement while computing points-to information. Storing complete context information can exponentially blow up the memory requirement and increase analysis time, making the analysis non-scalable for large programs.

It has been established that flow-sensitivity does not add a significant precision over a flow-insensitive analysis [15]. Therefore, we consider context-sensitive flow-insensitive points-to analysis in this paper A flow-insensitive points-to analysis iterates over a set of constraints obtained from points-to statements until it reaches a fixpoint. We observe that this phenomenon is similar in spirit to obtaining a solution to a system of linear equations. Each equation defines a constraint on the feasible solution and a linear solver progressively approaches the final solution in an iterative manner. Similarly, every points-to statement forms a constraint on the feasible points-to information and every iteration of a points-to analysis *refines* the points-to information obtained over the previous iteration. We exploit this similarity to *map* the input source program to a set of linear constraints, solve it using a standard linear equation solver and *unmap* the results to obtain the points-to information. As we show in the next section, a naive approach of converting points-to statements into a linear form faces several challenges due to (i) the distinction between ℓ-value and r-value in points-to statements, (ii) multiple dereferences of a pointer and (iii) the same variable defined in multiple statements. We address these challenges with novel mechanisms based on prime factorization of integers.

Major contributions of this paper are as below.

- We devise a novel representation based on prime factorization to store points-to information.
- We transform points-to constraints into a system of linear equations without affecting precision. We provide novel solutions to keep the equations linear in every iteration of the analysis and build an iterative inclusion-based context-sensitive points-to analysis based on the linear solver.
- We show the effectiveness of our approach by comparing it with state-of-the-art context-sensitive algorithms using SPEC 2000 benchmarks and two large open source programs (*httpd* and *sendmail*). On an average, our method computes points-to information in 55 seconds using 21 MB memory proving competitive to other methods.

More than the initial performance numbers, the real contribution of this work is the novel formulation which would open up a new way of performing points-to analysis and would greatly help in scaling the overall compilation. Further, linear algebra is a well researched topic. Several enhancements have been made to Gauss's cubic ($\mathtt{O}(\mathtt{n}^3)$) algorithm to solve a non-singular system of linear equations (see [26] for a survey). Strassen's surprising $\mathtt{O}(\mathtt{n}^{\log_2^7})$ algorithm[29] for matrix multiplication is one such example. Transforming points-to analysis into a linear system enables us to apply such powerful techniques (e.g., [8]) to scale the challenging task of points-to analysis.

2 Points-to Analysis.

In the following subsection, we describe a simple method to convert a set of points-to statements into a set of linear equations. Using it as a baseline, we discuss several challenges that such a method poses. Consequently, in Section 2.2, we introduce our novel transformation that addresses all the discussed issues and present our points-to analysis algorithm (Section 2.3). Later, we extend it for context-sensitivity using an invocation graph based approach (Section 2.4) and prove its soundness in Section 2.5. Finally, we describe how our novel representation of points-to information can improve client analyses (Section 2.6).

2.1 A First-cut Approach

Consider the set of C statements given in Figure 1(a). Let us define a transformation that translates $\&\mathtt{x}$ into $\mathtt{x}-1$ and $*^{\mathtt{k}}\mathtt{x}$ into $\mathtt{x}+\mathtt{k}$, where $\mathtt{k}$ is the number of '$*$'s used in dereferencing. Thus, $*\mathtt{x}$ is transformed as $\mathtt{x}+1$, $**\mathtt{x}$ as $\mathtt{x}+2$ and so on. A singleton variable without any operations is copied as it is, thus, $\mathtt{x}$ translates to $\mathtt{x}$. The transformed program now looks like Figure 1(b). This becomes a simple linear system of equations that can be written in matrix form $\mathtt{AX}=\mathtt{B}$ as shown in Figure 1(c).

This small example illustrates several interesting aspects. First, the choices of transformation functions for '$*$' and '&' are not independent, because '$*$' and '&' are complementary operations by language semantics, which should be carried to the linear transformation. Second, selecting $\mathtt{k}=0$ is not a good choice because we lose information regarding the address-of and dereference operations, resulting in loss of precision in the analysis. Third, every row in matrix $\mathtt{A}$ has at most two $\mathtt{1}$s, i.e., every equation has at most two unknowns. All the entries in matrices $\mathtt{A}$ and $\mathtt{B}$ are $\mathtt{0}$, $\mathtt{1}$ or $-\mathtt{1}$.

Solving the above linear system using a solver yields the following parameterized result: $\mathtt{y}=\mathtt{r}, \mathtt{a}=\mathtt{r}-1, \mathtt{p}=\mathtt{r}-2, \mathtt{b}=\mathtt{r}-1, \mathtt{c}=\mathtt{r}-1$.

From the values of the variables, we can quickly conclude that $\mathtt{a}$, $\mathtt{b}$ and $\mathtt{c}$ are aliases. Further, since the value of $\mathtt{p}$ is one greater than that of $\mathtt{a}$, we say that $\mathtt{p}$ points to $\mathtt{a}$, and in the same manner, $\mathtt{a}$ points to $\mathtt{y}$. Thus, our analysis

computes all the points-to information obtained using Andersen's analysis, and is thus *safe*: $\mathtt{y} \rightarrow \{\}, \mathtt{a} \rightarrow \{\mathtt{y}\}, \mathtt{p} \rightarrow \{\mathtt{a}\}, \mathtt{b} \rightarrow \{\mathtt{y}\}, \mathtt{c} \rightarrow \{\mathtt{y}\}$.

Next, we discuss certain issues with this approach.

Imprecise analysis. Note that our solver also added a few spurious points-to pairs: $\mathtt{p} \rightarrow \{\mathtt{b}, \mathtt{c}\}$. Therefore, the first-cut approach described above gives an *imprecise* result.

Inconsistent equations. The above approach fails for multiple assignments to the same variable. For instance, $\mathtt{a} = \&\mathtt{x}, \mathtt{a} = \&\mathtt{y}$ is a valid program fragment. However, $\mathtt{a} = \mathtt{x} - 1, \mathtt{a} = \mathtt{y} - 1$ does not form a consistent equation system unless $\mathtt{x} = \mathtt{y}$. This issue is discussed in the context of *bug-finding* [12].

Cyclic dependences. Note that each constraint in the above system of equations is of the form $\mathtt{a_i} - \mathtt{a_j} = \mathtt{b_{ij}}$ where $\mathtt{b_{ij}} \in \{0, 1, -1\}$. We can build a constraint graph $\mathtt{G} = (\mathtt{V}, \mathtt{E}, \mathtt{w})$ where

$\mathtt{V} = \{\mathtt{a_1}, ..., \mathtt{a_n}\} \cup \{\mathtt{a_0}\}$, $\mathtt{w}(\mathtt{a_i}, \mathtt{a_j}) = \mathtt{b_{ij}}a$, $\mathtt{w}(\mathtt{a_0}, \mathtt{a_i}) = 0$ and

$\mathtt{E} = \{(\mathtt{a_i}, \mathtt{a_j}) : \mathtt{a_i} - \mathtt{a_j} = \mathtt{b_{ij}}$ is a constraint$\} \cup \{(\mathtt{a_0}, \mathtt{a_1}), ..., (\mathtt{a_0}, \mathtt{a_n})\}$.

The above linear system has a feasible solution *iff* the corresponding constraint graph has no cycle with negative weight [3]. A linear solver outputs "no solution" for a system with a cycle. Our algorithm uses appropriate variable renaming that allows a standard linear solver to solve such equations.

Nonlinear system of equations. One way to handle inconsistent equations is to multiply the constraints having the same unknown to generate a non-linear set of equations. Thus, $\mathtt{a} = \&\mathtt{x}$ and $\mathtt{a} = \&\mathtt{y}$ would generate a non-linear constraint $(\mathtt{a} - \mathtt{x} + 1)(\mathtt{a} - \mathtt{y} + 1) = 0$. However, non-linear analysis is often more expensive than a linear analysis. Further, maintaining integral solutions across iterations using standard techniques is a difficult task.

Equations versus inequations. The inclusion-based analysis semantics for a points-to statement $\mathtt{a} = \mathtt{b}$ imply points-to-set(a) $\supseteq$ points-to-set(b). Transforming the statement into an equality $\mathtt{a} - \mathtt{b} = 0$ instead of an inequality can be imprecise, as equality in mathematics is bidirectional. It is easy to verify, however, that if a set of constraints contains each *ℓ-value* at most once *and* this holds across iterations of the analysis, the solution sets obtained using inequalities and equalities would be the same. We exploit this observation in our algorithm.

Dereferencing. As per our first-cut approach, transformations of points-to statements $\mathtt{a} = \&\mathtt{b}$ and $*\mathtt{a} = \mathtt{b}$ would be $\mathtt{a} = \mathtt{b} - 1$ and $\mathtt{a} + 1 = \mathtt{b}$ respectively. According to the algebraic semantics, the above equations are equivalent, although the two points-to statements have different semantics. This necessitates one to take care of the *store* constraints separately.

2.2 The Modified Approach

We solve the issues with the first-cut approach described in previous subsection with a modified mechanism. We use the following example to illustrate it.

$\mathtt{a} = \&\mathtt{x}; \mathtt{b} = \&\mathtt{y}; \mathtt{p} = \&\mathtt{a}; \mathtt{c} = *\mathtt{p}; *\mathtt{p} = \mathtt{b}; \mathtt{q} = \mathtt{p}; \mathtt{p} = *\mathtt{p}; \mathtt{a} = \mathtt{b}.$

Pre-processing. First, we move *store* constraints from the set of equations to a set of generative constraints (as they *generate* more linear equations) and are processed specially. We proceed with the remaining non-*store* constraints.

Second, all constraints of the form $\mathtt{v} = \mathtt{e}$ are converted to $\mathtt{v} = \mathtt{v_{i-1}} \oplus \mathtt{e}$. $\mathtt{v_{i-1}}$ is the value of the variable $\mathtt{v}$ obtained in the last iteration. Initially, $\mathtt{v} = \mathtt{v_0} \oplus \mathtt{e}$. This transformation ensures monotonicity required for a flow-insensitive points-to analysis. The operator $\oplus$ would be concretized shortly. $\mathtt{v_0}$ is a constant, since it is already computed from the previous iteration.

Next, we assign unique prime numbers from a select set $\mathcal{P}$ to the right-hand side expression in each address-of constraint. We defer the definition of $\mathcal{P}$ to a later part of this subsection. Thus, $\&\mathtt{x}, \&\mathtt{y}$ and $\&\mathtt{a}$ are assigned arbitrary prime numbers, say $\&\mathtt{x} = 17; \&\mathtt{x} = 29$; and $\&\mathtt{a} = 101$. The addresses of the remaining variables $(\mathtt{b}, \mathtt{p}, \mathtt{q}, \mathtt{c})$ are assigned a special sentinel value χ. Further, all the variables of the form $\mathtt{v}$ and $\mathtt{v_i}$ are assigned an initial r-value of χ. Thus, $\mathtt{x}, \mathtt{y}, \mathtt{a}, \mathtt{b}, \mathtt{c}, \mathtt{p}, \mathtt{q}$ and $\mathtt{x_0}$, $\mathtt{y_0}$, $\mathtt{a_0}$, $\mathtt{b_0}$, $\mathtt{c_0}$, $\mathtt{p_0}, \mathtt{q_0}$ equal χ. We keep two-way maps of variables to their r-values and addresses. This step is performed only once in the analysis. In the rest of the paper, the term "address of a variable" refers to the prime number assigned to it by our static analysis.

Next, the dereference in every load statement $\mathtt{p} = *\mathtt{q}$ is replaced by expression $\mathtt{q_{i-1}} + 1$ where $\mathtt{i}$ is the current iteration. Therefore, $\mathtt{c} = *\mathtt{p}$ becomes $\mathtt{c} = \mathtt{c_0} \oplus (\mathtt{p_0}{+}1)$ and $\mathtt{p} = *\mathtt{p}$ becomes $\mathtt{p} = \mathtt{p_0} \oplus (\mathtt{p_0} + 1)$. Note that by generating different versions of the same variable in this manner, we remove cyclic dependences altogether, since variables $\mathtt{v_i}$ are not dependent on any other variable as they are never *defined* explicitly in the constraints. The renaming is only symbolic and appears only for exposition purposes. Since values from only the previous iteration are required, we simply make a copy $\mathtt{v_{copy}}$ for each variable $\mathtt{v}$ at the start of each iteration.

Last, we rename multiple occurrences of the same variable as an *ℓ-value* in different constraints to convert it to an SSA-like form. For each such renamed variable $\mathtt{v'}$, we store a constraint of the form $\mathtt{v} = \mathtt{v'}$ in a separate merging constraint set. Thus, assignments to $\mathtt{a}$ in $\mathtt{a} = \mathtt{x_0}$ and $\mathtt{a} = \mathtt{b_0}$ are replaced as $\mathtt{a} = \mathtt{x_0}$ and $\mathtt{a'} = \mathtt{b_0}$ and the constraint $\mathtt{a} = \mathtt{a'}$ is added to the merging constraints set. The constraints now look as follows.

Linear constraints: $\mathtt{a} = \mathtt{a_0} \oplus \&\mathtt{x}; \mathtt{b} = \mathtt{b_0} \oplus \&\mathtt{y}; \mathtt{p} = \mathtt{p_0} \oplus \&\mathtt{a};$
$\mathtt{c} = \mathtt{c_0} \oplus (\mathtt{p_0} + 1); \mathtt{q} = \mathtt{q_0} \oplus \mathtt{p}; \mathtt{p'} = \mathtt{p_0} \oplus (\mathtt{p_0} + 1); \mathtt{a'} = \mathtt{a_0} \oplus \mathtt{b}.$
Generative constraints: $*\mathtt{p} = \mathtt{b}.$
Merging constraints: $\mathtt{a} = \mathtt{a'}; \mathtt{p} = \mathtt{p'}.$

Substituting the r-values and the primes for the addresses of variables, we get
$\mathtt{a} = \chi \oplus 17, \mathtt{b} = \chi \oplus 29, \mathtt{p} = \chi \oplus 101, \mathtt{c} = \chi \oplus (\chi + 1),$
$\mathtt{q} = \chi \oplus \mathtt{p}, \mathtt{p'} = \chi \oplus (\chi + 1), \mathtt{a'} = 101 \oplus \mathtt{b}.$

χ and $\oplus$. We unfold the mystery behind the values of χ and $\oplus$ now. The rationale behind replacing the address of every address-taken variable with a

prime number is to have a *non-decomposable* element defining the variable. We make use of *prime factorization* of integers to map a value to the corresponding points-to set. The first trivial but important observation towards this goal is that any pointee of any variable has to appear as address taken in at least one of the constraints. Therefore, the only pointees any pointer can have would exactly be the address-taken variables. Thus, a *composition* $\mathtt{v} = \mathtt{v_i} \oplus \mathtt{v_j} \oplus ...$ of the primes $\mathtt{v_i}, \mathtt{v_j}, ...$ representing address-taken variables defines the pointer $\mathtt{v}$ pointing to all these address-taken variables. The composition is defined by operator $\oplus$ and it defines a lattice over the finite set of all the pointers and pointees (Figure 1(d)). The top element $\top$ defines a composition of all address-taken variables ($\mathtt{v_0} \oplus \mathtt{v_1} \oplus ... \oplus \mathtt{v_n}$) and the bottom element $\bot$ defines the empty set. Since we use prime factorization, $\oplus$ becomes the multiplication operator $\times$ and χ is the identity element, i.e., $\mathtt{1}$. The reason behind using $\oplus$ and χ as placeholders is that it is possible to use an alternate lattice with different $\oplus$ and χ and achieve an equivalent transformation (as long as the equations remain linear). Since every positive integer has a unique prime factorization, we guarantee that the value of a pointer uniquely identifies its pointees. For instance, if $\mathtt{a} \rightarrow \{\mathtt{x}, \mathtt{y}\}$ and $\mathtt{b} \rightarrow \{\mathtt{y}, \mathtt{z}, \mathtt{w}\}$, then we can assign primes to $\&\mathtt{x}, \&\mathtt{y}, \&\mathtt{z}, \&\mathtt{w}$ arbitrarily as $\&\mathtt{x} = 11, \&\mathtt{y} = 19, \&\mathtt{z} = 5, \&\mathtt{w} = 3$ and the values of $\mathtt{a}$ and $\mathtt{b}$ would be calculated as $\mathtt{a} = 11 \times 19 = 209$ and $\mathtt{b} = 19 \times 5 \times 3 = 285$. Since, $\mathtt{209}$ can only be factored as $\mathtt{11} \times \mathtt{19}$ and $\mathtt{285}$ does not have any other factorization than $\mathtt{19} \times \mathtt{5} \times \mathtt{3}$, we can obtain the points-to sets for pointers $\mathtt{a}$ and $\mathtt{b}$ from the factors.

Unfortunately, prime factorization is not known to be polynomial [18]. Therefore, for efficiency reasons, our implementation keeps track of the factors explicitly. We use a prime-factor-table for this purpose. The prime-factor-table stores all the prime factors of a value. We initially store all the primes p corresponding to the address-taken variables as $\mathtt{p} = \mathtt{p} \times \mathtt{1}$.

Only the chosen primes along with their compositions denote a computed points-to set. Typically, the number of dereferences in real-world programs is very small (< 5). All other values denote one or more dereferences (e.g., $**\mathtt{p}$) over the compositions. By careful offline selection of primes, our analysis guarantees that a certain $\mathtt{k}$ number of dereferences will never *overlap* with one another. In fact, we define our method for upto $\mathtt{k}$ levels of dereferencing, for a fixed value of $\mathtt{k}$. Our prime number set $\mathcal{P}$ is also defined for a specific $\mathtt{k}$. More specifically, for any prime numbers $\mathtt{p} \in \mathcal{P}$, the products of any one[1] or more $\mathtt{p}$ are distance more than $\mathtt{k}$ apart. Thus, $|\mathtt{p_i} - \mathtt{p_j}| > \mathtt{k}$ and $|\mathtt{p_i} * \mathtt{p_j} - \mathtt{p_l} * \mathtt{p_m}| > \mathtt{k}$ and $|\mathtt{p_i} * \mathtt{p_j} * \mathtt{p_l} - \mathtt{p_m} * \mathtt{p_n} * \mathtt{p_o}| > \mathtt{k}$ and so on. Note that $\mathcal{P}$ needs to be computed only once, offline. The lattice for the prime number set $\mathcal{P}$ chosen for $k = 5$ is shown in Figure 1(d). Here, the bracketed values, e.g., (12,13,...,16) denote possible dereferencings of a variable which is assigned the value 11.

Thus, the system of equations now becomes

Linear constraints: $\mathtt{a} = \mathtt{17}; \mathtt{b} = \mathtt{29}; \mathtt{p} = \mathtt{101}; \mathtt{c} = \mathtt{2}; \mathtt{q} = \mathtt{p}; \mathtt{p'} = \mathtt{2}; \mathtt{a'} = \mathtt{101} \times \mathtt{b}$.

Generative constraints: $*\mathtt{p} = \mathtt{b}$. Merging constraints: $\mathtt{a} = \mathtt{a'}; \mathtt{p} = \mathtt{p'}$.

[1] product of one number is the number itself.

Solving the system. Solving the above system of equations using a standard linear solver gives us the following solution.

$\mathtt{a} = 17, \mathtt{b} = 29, \mathtt{p} = 101, \mathtt{c} = 2, \mathtt{q} = 101, \mathtt{p}' = 2, \mathtt{a}' = 101 \times 29.$

The solver returns each value as a single integer (e.g., 2929) and not as factors (e.g., 101×29). Our analysis finds the prime factors using prime-factor-table. We prove three essential properties of the solution now.

Feasibility. By renaming the variable occurring in multiple assignments as $\mathtt{a}', \mathtt{a}'', ...$, we guarantee at most one definition per variable. Further, all constants involved in the equations are positive. Thus, there is no negative weight cycle in the constraint graph — in fact, there is neither a cycle nor a negative weight. This guarantees a feasible solution to the system.

Uniqueness. A variable attains a unique value if it is defined exactly once. Our initialization of all the variables to the value of $\chi = 1$ followed by the variable renaming assigns a unique value to each variable. For instance, let the system have only one constraint: $\mathtt{a} = \mathtt{b}$. In general, this system has infinite number of solutions because $\mathtt{b}$ is not restricted to any value. In our analysis, we initialize both ($\mathtt{a}$ and $\mathtt{b}$) to 1.

Integrality. We are solving (and not optimizing) a system of equations that involves only addition, subtraction and multiplication over positive integers ($\mathtt{v_i}$ and constants). Further, each equation is of the form $\mathtt{v} = \mathtt{v_i} \times \mathtt{e}$ where both $\mathtt{v_i}$ and $\mathtt{e}$ are integral. Hence the system guarantees an integral solution.

Post-processing. Interpreting the values in the above solution obtained using a linear solver is straightforward except for those of $\mathtt{c}$ and $\mathtt{p}'$. In the simple case, a value $\mathtt{v} + \mathtt{k}$ denotes $\mathtt{k}^{\mathtt{th}}$ dereference of $\mathtt{v}$. To find $\mathtt{v}$, our method checks each value ϑ in $(\mathtt{v} + \mathtt{k}), (\mathtt{v} + \mathtt{k} - 1), (\mathtt{v} + \mathtt{k} - 2), ...$ in the prime factor table. For the first ϑ that appears in the prime factor table, $\mathtt{v} = \vartheta$ and $\mathtt{k}' = \mathtt{v} + \mathtt{k} - \vartheta$ represents the level of dereferencing. We obtain the prime factors of ϑ from the table, which would correspond to the addresses of variables, reverse-map the addresses to their corresponding variables, then obtain the r-values of the variables from the map, whose prime factors would denote the points-to set we want for expression $\mathtt{v} + \mathtt{k}$. Another level of reverse mapping-mapping would be required for $\mathtt{k} = 2$ and so on. We explain dereferencing (Algorithm 3) later.

Although the above sequential procedure may theoretically require us to search through a large number of values for $\mathtt{k}$, in practice, $\mathtt{k}$ is very small. This is because the number of dereferences in a program (like $\mathtt{**p}$) is very small.

The value 2 of the variables $\mathtt{c}$ and $\mathtt{p}'$ is represented as $1 + 1$ where the second 1 denotes a dereference and the first 1 is the value of the variable being dereferenced. In this case, since $\mathtt{v} = 1$, which is the sentinel χ, its dereference results in an empty set and thus, both $\mathtt{c}$ and $\mathtt{p}'$ are assigned a value of 1.

The next step is to merge the points-to sets of renamed variables, i.e., evaluating merging constraints. This changes $\mathtt{a}$ and $\mathtt{p}$ as $\mathtt{a} = 17 \times 101 \times 29$ and $\mathtt{p} = 101 \times 1 = 101$. After merging, we discard all the renamed variables.

Thus, at the end of the first iteration, the points-to set contained in the values is: $x \to \{\}, y \to \{\}, a \to \{x\}, b \to \{y\}, c \to \{\}, p \to \{a\}, q \to \{a\}$.

The final step is to evaluate the generative constraints and generate more linear constraints. Thus, the store constraint $*\mathtt{p} = \mathtt{b}$ generates the constraint $\mathtt{a} = \mathtt{b}$ (because $\mathtt{p}$ points to $\mathtt{a}$) which we add to the set of linear constraints to be processed in the next iteration. Note that the generative constraints set is retained as more constraints may need to be added in further iterations. Since the values of the variables have changed, next iteration is required.

Subsequent iterations. The constraints, ready for iteration number two, are

Linear constraints: $\mathtt{a} = \mathtt{a}_1 \times \&\mathtt{x}_1; \mathtt{b} = \mathtt{b}_1 \times \&\mathtt{y}_1; \mathtt{p} = \mathtt{p}_1 \times \&\mathtt{a}_1;$
$\mathtt{c} = \mathtt{c}_1 \times (\mathtt{p}_1 + 1); \mathtt{q} = \mathtt{q}_1 \times \mathtt{p}; \mathtt{p}' = \mathtt{p}_1 \times (\mathtt{p}_1 + 1); \mathtt{a}' = \mathtt{a}_1 \times \mathtt{b}; \mathtt{a}'' = \mathtt{a}_1 \times \mathtt{b}.$

Generative constraints: $*\mathtt{p} = \mathtt{b}$.

Merging constraints: $\mathtt{a} = \mathtt{a}'; \mathtt{a} = \mathtt{a}''; \mathtt{p} = \mathtt{p}'$.

Here, $\mathtt{v}_1$ is the value of the variable $\mathtt{v}$ obtained in iteration 1. Thus the constraints to be solved by the linear solver are:

$\mathtt{a} = 17 \times 17, \mathtt{b} = 29 \times 29, \mathtt{p} = 101 \times 101, \mathtt{c} = 101 + 1,$
$\mathtt{q} = 101 \times \mathtt{p}, \mathtt{p}' = 101 \times (101 + 1), \mathtt{a}' = 17 \times \mathtt{b}, \mathtt{a}'' = 17 \times \mathtt{b}.$

The linear solver offers the following solution.

$\mathtt{a} = 17 \times 17, \mathtt{b} = 29 \times 29, \mathtt{p} = 101 \times 101, \mathtt{c} = 102,$
$\mathtt{q} = 101 \times 101 \times 101, \mathtt{p}' = 101 \times 102, \mathtt{a}' = 17 \times 29 \times 29, \mathtt{a}'' = 17 \times 29 \times 29.$

Post-processing over the values starts with *pruning the powers* of the values containing repeated prime factors as they do not add any additional points-to information to the solution. Thus,

$\mathtt{a} = 17, \mathtt{b} = 29, \mathtt{p} = 101, \mathtt{c} = 102, \mathtt{q} = 101, \mathtt{p}' = 101 \times 102, \mathtt{a}' = 17 \times 29, \mathtt{a}'' = 17 \times 29.$

The next step is to dereference variables to obtain their points-to sets. Since, 17, 29, and 101 are directly available in prime factor table, the values of $\mathtt{a}, \mathtt{b}, \mathtt{p}, \mathtt{q}$ do not require a dereference. In case of $\mathtt{c}$, 102 is not present in prime factor table, so the next value 101 is searched for, which indeed is present in the table. Thus, $(102 - 101)$ dereferences are done on 101. Further, 101 reverse-maps to $\&\mathtt{a}$ and $\mathtt{a}$ forward-maps to the r-value 17. Hence $\mathtt{c} = 17$, suggesting that $\mathtt{c}$ points to $\mathtt{x}$.

The value of $\mathtt{p}'$ is an interesting case. The solution returned by the solver (10302) is neither a prime number, nor a short offset from the product of primes. Rather, it is a product of a prime and a short offset of the prime. We know that it is the value of variable $\mathtt{p}'$ whose original value was $\mathtt{p}_1 = 101$. This original value is used to find out the points-to set contained in value 10302. To achieve this, our method (always) divides the value obtained by the solver by the original value of the variable ($\mathtt{p}'$ maps to $\mathtt{p}$ whose original value is $\mathtt{p}_1 = 101$). Thus, we get $10302/101 = 102$. Our method then applies the dereferencing algorithm on 102 to get its points-to set, which, as explained above for $\mathtt{c}$, computes the value 17 corresponding to the variable $\mathtt{x}$. This updates $\mathtt{p}'$ to 101×17.

It should be emphasized that our method never checks a number for primality. After prime-factor-table is initially populated with statically defined primes as a multiple of self and unity, a lookup in the table suffices for primality testing.

The next step is to evaluate the merging set to obtain the following.
$\mathtt{a} = 17 \times 17 \times 29, \mathtt{a} = (17 \times 17 \times 29) \times (17 \times 29), \mathtt{p} = (101 \times 101) \times (101 \times 17)$,
which on pruning gives $\mathtt{a} = 17 \times 29, \mathtt{p} = 101 \times 17$.

Thus, at the end of the second iteration, the points-to set contained in the values is as follows.

$\mathtt{x} \rightarrow \{\}, \mathtt{y} \rightarrow \{\}, \mathtt{a} \rightarrow \{\mathtt{x}, \mathtt{y}\}, \mathtt{b} \rightarrow \{\mathtt{y}\}, \mathtt{c} \rightarrow \{\mathtt{x}\}, \mathtt{p} \rightarrow \{\mathtt{a}, \mathtt{x}\}, \mathtt{q} \rightarrow \{\mathtt{a}, \mathtt{x}\}$.
Executing the final step of evaluating the generative constraints, we obtain an additional linear constraint: $\mathtt{x} = \mathtt{b}$.
Following the same process, at the end of the third iteration we get $\mathtt{x} = 29, \mathtt{y} = 1$, $\mathtt{a} = 17 \times 29, \mathtt{b} = 29, \mathtt{c} = 17 \times 29, \mathtt{p} = 17 \times 29 \times 101, \mathtt{q} = 17 \times 29 \times 101$ which corresponds to the points-to set
$\mathtt{x} \rightarrow \{\mathtt{y}\}, \mathtt{y} \rightarrow \{\}, \mathtt{a} \rightarrow \{\mathtt{x}, \mathtt{y}\}, \mathtt{b} \rightarrow \{\mathtt{y}\}, \mathtt{c} \rightarrow \{\mathtt{x}, \mathtt{y}\}, \mathtt{p} \rightarrow \{\mathtt{a}, \mathtt{x}, \mathtt{y}\}, \mathtt{q} \rightarrow \{\mathtt{a}, \mathtt{x}, \mathtt{y}\}$
and a generative constraint $\mathtt{y} = \mathtt{b}$.

At the end of the fourth iteration, the method results in $\mathtt{x} = 29, \mathtt{y} = 29, \mathtt{a} = 17 \times 29$, $\mathtt{b} = 29, \mathtt{c} = 17 \times 29, \mathtt{p} = 17 \times 29 \times 101, \mathtt{q} = 17 \times 29 \times 101$ which corresponds to the points-to set
$\mathtt{x} \rightarrow \{\mathtt{y}\}, \mathtt{y} \rightarrow \{\mathtt{y}\}, \mathtt{a} \rightarrow \{\mathtt{x}, \mathtt{y}\}, \mathtt{b} \rightarrow \{\mathtt{y}\}, \mathtt{c} \rightarrow \{\mathtt{x}, \mathtt{y}\}, \mathtt{p} \rightarrow \{\mathtt{a}, \mathtt{x}, \mathtt{y}\}, \mathtt{q} \rightarrow \{\mathtt{a}, \mathtt{x}, \mathtt{y}\}$
with no additional generative constraint.

The fifth iteration makes no change to the values of the variables suggesting that a fixpoint solution is reached.

2.3 The Algorithm

Our points-to analysis is outlined in Algorithm 1. To avoid clutter, we have removed the details of pruning of powers, which is straightforward. The analysis assumes availability of the set of constraints `C` and the set of variables `V` used in `C`. An important data structure is the prime-factor-table which is implemented as a hash-table mapping a key to a set of prime numbers that form the factors of the key. Insertion of the tuple ($\mathtt{a} \times \mathtt{b}$, $\mathtt{a}$, $\mathtt{b}$) assumes existence of $\mathtt{a}$ and $\mathtt{b}$ in the table (our analysis guarantees that) if $\mathtt{a}$ or $\mathtt{b}$ is not unity, and is done by combining the prime factors for $\mathtt{a}$ and $\mathtt{b} \in \mathcal{P}$ from the table.

Lines 1–3 perform initialization of variables. Lines 4–16 preprocess the constraints. Lines 18–46 solve the linear equations iteratively until a fixpoint as described in the last subsection. An important step of interpreting the solution is done in Lines 33–35 using Algorithm 3. The algorithm checks for an entry of a variable's value in the prime-factor-table to see if it is a valid composition of primes. If yes, then no dereferencing is required and the value is returned as it is (Lines 3–4 of Algorithm 3). Otherwise, the value is divided by the original value of the variable at the start of the iteration ($\mathtt{v}_{\mathtt{copy}}$). If the quotient is not found in prime-factor-table then it implies one or more dereferences. A linear downward search from the value of the variable is performed for existence in the prime-factor-table (Lines 11–13). The number of entries visited in the process denotes the number of dereferences to be performed. The dereferencing is done by unmapping from the primes corresponding to the addresses of variables and then

Algorithm 1 Points-to analysis as a system of equations.

Require: set C of points-to constraints, set V of variables
Ensure: each variable in V has a value indicating its points-to set

      return v
 5: else if v/v_copy ∈ prime-factor-table then
      prime-factor-table.insert(v, v_copy, v/v_copy)
      return v
    else
      v = v/v_copy
10:   k = 1
      while (v − k) ∉ prime-factor-table do
        ++k
      end while
      v = (v − k)
15:   for i = 1 to k do
        S = get-points-to(v, prime-factor-table) {Algo. 2}
        prod = 1
        for all s ∈ S and s ≠ 1 do
          r = reverse-lvalue(s)
20:       prod = prod × r
          prime-factor-table.insert(prod, prod/r, r)
        end for
        v = prod
      end for
25: end if
    return v × v_copy
```

mapping the variables to their r-values (Line 19 of Algorithm 3). The composition obtained at the end of this procedure denotes the new pointees computed in the current iteration. That, multiplied by $\mathtt{v}_{\mathtt{copy}}$, is the new value of v.

Both Algorithms 1 and 3 make use of Algorithm 2 for computing points-to set of a pointer. It finds the prime factors of the r-value of the pointer (Line 2) followed by an unmapping from the primes to the corresponding variables (Line 4).

At the end of Algorithm 1, the r-values of variables in V denote their computed points-to sets. C is no longer required. If a client does not need a pointer's points-to set then prime-factor-table can be freed.

Implementation issue. Similar to other works on finding linear relationships among program variables [4, 21], our analysis suffers from the issue of large values. Since we store points-to set as a multiplication of primes, the resulting values quickly go beyond the integer range of 64 bits. Hence we are required to use an integer library that emulates integer arithmetic over large unsigned integers.

2.4 Context-Sensitive Analysis

We extend Algorithm 1 for context-sensitivity using an invocation graph based approach [7]. An invocation graph based analysis enables us to disallow non-realizable interprocedural execution paths. We handle recursion by iterating over the cyclic call-chain and computing a fixpoint of the points-to tuples over the cycle. Our analysis is field-insensitive, i.e., we assume that any reference to a

field inside a structure is to the whole structure. The context-sensitive version is outlined in recursive Algorithm 4 (Appendix C).

2.5 Safety and Precision

Safety implies that our algorithm computes a superset of the information computed by an inclusion-based analysis. Precision implies that our analysis does not compute a proper superset of the information.

Theorem 1: *The analysis is safe for a given dereferencing level k.*

Theorem 2: *The analysis is precise for a given dereferencing level k.*
See Appendix A for the proofs.

2.6 Client Analyses

Several clients (e.g., constant propagation, parallelism extractors, etc.), which use points-to analysis, query for alias information. Thus, an alias query *alias(*`p`*,* `q`*)* should return a boolean value depending upon whether pointers `p` and `q` share any pointee. The query can be easily answered by finding the greatest common divisor (GCD) of pointers `p` and `q`. If the GCD is 1, the pointers do not alias; otherwise, they alias.

A useful form of Mod/Ref analysis is to find out what all global (or heap) variables are only referenced and not modified by any pointers in the program. This helps in finding out the read-only globals and is immensely helpful in parallelization of programs. A first step towards this goal is to find all pointers pointing to a given set of (global or heap) variables. Searching for the variables of interest in a sparse pointee list of a pointer would be costly. In contrast, if the underlying representation is using a composition of primes to represent points-to information, then we simply need to check whether for each variable `v` of interest, the address-value of `v` divides the r-value of the pointer. Thus, a representation based on prime factorization helps in speeding up the client analyses.

3 Experimental Evaluation

We evaluate the effectiveness of our approach using 16 SPEC C/C++ benchmarks and two large open source programs, namely *httpd* and *sendmail*. The characteristics of the benchmark programs are given in Table 2 (Appendix B). *KLOC* is the kilo lines of unprocessed source code. *Total Inst* is the total number of three address code instructions after optimizing at -O2 level. *Pointer Inst* is the total number of pointer instructions that get processed by the analysis. *Func* is the number of functions in each program. *Contexts* is the total number of calling contexts in each program. The product of primes can quickly go beyond 64-bits. Hence we use GNU MP Bignum Library to represent the composition of primes. For solving equations, we use C++ language extension of CPLEX®

solver from IBM ILOG toolset [16]. We compare our approach, referred to as *linear*, with the following implementations.

- *anders*: This is the base Andersen's algorithm[1] that uses a simple iterative procedure over the points-to constraints to reach a fixpoint solution. The underlying data structure used is a sorted vector of pointees per pointer. We extend it for context-sensitivity using Algorithm 4.
- *bloom*: The bloom filter method uses an approximate representation for storing both the points-to facts and the context information using a bloom filter. As this representation results in false-positives, the method is approximate and introduces some loss in precision. For our experiments, we use the *medium* configuration [22] which results in roughly 2% of precision loss for the chosen benchmarks.
- *bdd*: This is the *Lazy Cycle Detection*(LCD) algorithm implemented using Binary Decision Diagrams (BDD) from Hardekopf and Lin [13]. We extend it for context-sensitivity.

Analysis time. The analysis times in seconds required for each benchmark by different methods are given in Table 1. The analysis time is composed of reading an input points-to constraints file, applying the analysis over the constraints and computing the final points-to information as a fixpoint.

From Table 1, we observe that *anders* goes out of memory (*OOM*) for three benchmarks: *gcc*, *perlbmk* and *vortex*. For these three benchmarks *linear* obtains the points-to information in 1–3 minutes. Further comparing the analysis time of *anders*, *bdd* and *bloom* with those of *linear*, we find that *linear* takes considerably less time for most of the benchmarks. The average analysis time per benchmark is lower for *linear* by a factor of 20 when compared to *bloom* and by 30 when compared to *bdd*. Only in the case of *sendmail, mesa, twolf* and *ammp*, the analysis time of *bloom* is significantly better. It should be noted here that *bloom* has 2% precision loss in these applications [22] compared to *anders*, *bdd* and *linear*. Last, the analysis time of *linear* is 1–2 orders of magnitude smaller than *anders*, *bdd* or *bloom*, especially for large benchmarks (*gcc, perlbmk, vortex* and *eon*). We believe that the analysis time of *linear* can be further improved by taking advantage of sharing of tasks across iterations and by exploiting properties of simple linear equations in the linear solver.

Memory. Memory requirement in KB for the benchmarks is given in Table 1. *anders* goes out of memory for three benchmarks: *gcc*, *perlbmk* and *vortex*, suggesting a need for a scalable points-to analysis. *bloom*, *bdd* and *linear* successfully complete on all benchmarks. Similar to the analysis time, our approach *linear* outperforms *anders* and *bloom* in memory requirement especially for large benchmarks. The *bdd* method, which is known for its space efficiency, uses the minimum amount of memory. On an average, *linear* consumes 21MB requiring maximum 69MB for *gcc*. This is comparable to *bdd*'s average memory requirement of 12MB and maximum of 23MB for *gcc*. This small memory requirement is a key aspect that allows our method to scale better with program size.

Benchmark	Time(sec)				Memory(KB)

Table 1: Time(seconds) and memory(KB) required for context-sensitive analysis.

Query time. We measured the amount of time required to answer an alias query *alias(p,q)*. The answer is a boolean value depending upon whether pointers p and q have any common pointee. *linear* uses GCD-based algorithm to answer the query. *anders* uses a sorted vector of pointees per pointer that needs to be traversed to find a common pointee. We used a set of ${}^nP_2$ queries over the set of all n pointers in the benchmark programs. Since it simply involves a small number of number-crunching operations, *linear* outperforms *anders*. We found that the average query time for *linear* is 0.85ms compared to 1.496ms for *anders*.

4 Related Work

The area of points-to analysis is rich in literature. See [15] for a survey. We mention only the most relevant related work in this section.

Points-to analysis. Most scalable algorithms proposed are based on unification[28][10]. Steensgaard[28] proposed an almost linear time algorithm that has been shown to scale to millions of lines of programs. However, precision of unification based approaches has always been an issue. Inclusion based approaches[1] that work on subsumption of points-to sets rather than a bidirectional similarity offer a better precision at the cost of theoretically cubic complexity. Recently, [27] showed it to be close to quadratic in practice. Several techniques[2][14][20][30] have been proposed to improve upon the original work by Andersen. [2] extracts

similarity across points-to sets while [30] exploits similarity across contexts to make brilliant use of Binary Decision Diagrams to store information in a succinct manner. The idea of *bootstrapping*[17] first reduces the problem by partitioning the set of pointers into disjoint alias sets using a fast and less precise algorithm (e.g., [28]) and later running more precise analysis on each of the partitions. Complete context-sensitivity requires huge amount of storage and analysis time. Therefore, approximate representations were introduced to trade off precision for scalability. [5] proposed *one level flow*, [19] unified contexts, while [22] hashed contexts to alleviate the need to store complete context information. Various enhancements have also been made for the inclusion-based analyses: online cycle elimination[9] to break dependence cycles on the fly and offline variable substitution[24] to reduce the number of pointers tracked during the analysis.

Program analysis using linear algebra. An important use of linear algebra in program analysis has been to compute affine relations among program variables[21]. [4] applied abstract interpretation for discovering equality or inequality constraints among program variables. However these methods are not applicable to pointer dereferences. [11] proposed an SML based solver for computing a partial approximate solution for a general system of equations used in logic programs. Another area where analyses based on linear systems has been used is in finding security vulnerabilities. [12] proposed a context-sensitive light-weight analysis modeling string manipulations as a linear program to detect buffer overrun vulnerabilities. [6] presented a C String Static Verifyer (CSSV) tool to find string manipulation errors. It converts a program written in a restricted subset of C into an integer program with assertions. A violation of an assertion signals a possible vulnerability. Recently, [8] proposed Newtonian Program Analysis as a generic method to solve iterative program analyses using Newton's method.

5 Conclusion

In this paper, we proposed a novel approach to transform a set of points-to constraints into a system of linear equations using prime factorization. We overcome the technical challenges by partitioning our inclusion-based analysis into a linear solver phase and a post-processing phase that interprets the resulting values and updates points-to information accordingly. The novel way of representing points-to information as a composition of primes allows us to keep the equations linear in every iteration. We show that our analysis is safe and precise for a fixed dereference level. Using a set of 16 SPEC 2000 benchmarks and two large open source programs, we show that our approach is not only feasible, but is also competitive to the state of the art solvers. More than the performance numbers reported here the main contribution of this paper is the novel formulation of points-to analysis as a linear system based on prime factorization. In future, we would like to apply enhancements proposed for linear systems to our analysis and improve the analysis time.

A Safety and Precision Proofs

Safety implies that our algorithm computes a superset of the information computed by an inclusion-based analysis. Precision implies that our analysis does not compute a proper superset of the information.

Lemma 1.1: *The analysis in Algorithm 1 is monotonic.*
Proof: Every address-taken variable is represented using a distinct prime number. Second, every positive integer has a unique prime factorization. Thus, our representation does not lead to a precision loss. Multiplication by an integer corresponds to including addresses represented by its prime factors. Division by an integer maps to the removal of the unique addresses represented by its prime factors. Multiplying the equations by $\mathtt{v_{copy}}$ iteration $\mathtt{i}$ (Lines 25 and 27) thus ensures encompassing the points-to set computed in iteration $\mathtt{i}-\mathtt{1}$. The only division is done in Algorithm 3 (Line 9) (which is guaranteed to be without a remainder and hence no information loss), but the product is restored in Line 26. Thus, no points-to information is ever killed and we guarantee monotonicity.

Lemma 1.2: *Address-of statements are transformed safely.*
Proof: The effect of address-of statement is computed by assigning the prime number of the address-taken variable to the r-value of the destination variable (Lines 5–9 of Algorithm 1).

Lemma 1.3: *Variable renaming is safe.*
Proof: Per constraint based semantics, statements $\mathtt{a}=\mathtt{e_1}, \mathtt{a}=\mathtt{e_2}$, ..., $\mathtt{a}=\mathtt{e_n}$ mean $\mathtt{a}\supseteq\mathtt{e_1}, \mathtt{a}\supseteq\mathtt{e_2}, ..., \mathtt{a}\supseteq\mathtt{e_n}$ which implies $\mathtt{a}\supseteq(\mathtt{e_1}\cup\mathtt{e_2}\cup...\cup\mathtt{e_n})$. Renaming gives $\mathtt{a'}=\mathtt{e_1}, \mathtt{a''}=\mathtt{e_2}, ..., \mathtt{a'^n}=\mathtt{e_n}$ adds constraints $\mathtt{a'}\supseteq\mathtt{e_1}, \mathtt{a''}\supseteq\mathtt{e_2}, ..., \mathtt{a'^n}\supseteq\mathtt{e_n}$ which implies $(\mathtt{a'}\cup\mathtt{a''}\cup...\cup\mathtt{a'^n})\supseteq(\mathtt{e_1}\cup\mathtt{e_2}\cup...\cup\mathtt{e_n})$. Merging the variables as

$\mathtt{a} = \mathtt{a}', \mathtt{a} = \mathtt{a}'', ..., \mathtt{a} = \mathtt{a}'^{\mathtt{n}}$ adds constraint $\mathtt{a} \supseteq (\mathtt{a}' \cup \mathtt{a}'' \cup ... \cup \mathtt{a}'^{\mathtt{n}})$. By transitivity of $\supseteq$, $\mathtt{a} \supseteq (\mathtt{e}_1 \cup \mathtt{e}_2 \cup ... \cup \mathtt{e}_\mathtt{n})$. Thus, variable renaming is safe.
Corollary 1.1: *Copy statements are transformed safely.*

Lemma 1.4: *Store statements are transformed safely.*
Proof: We define a points-to fact $\mathtt{f}$ to be *realizable* by a constraint $\mathtt{c}$ if evaluation of $\mathtt{c}$ *may* result in the computation of $\mathtt{f}$. $\mathtt{f}$ is *strictly-realizable* by $\mathtt{c}$ if for the computation of $\mathtt{f}$, evaluation of $\mathtt{c}$ is a *must*. For the sake of contradiction, assume that there is a valid points-to fact $\mathtt{a} \rightarrow \{\mathtt{x}\}$ that is strictly-realizable by the store constraint $\mathtt{a} = *\mathtt{p}$ and that does not get computed in our algorithm. Since the store statement, added to the generative constraint set, adds copy constraints $\mathtt{a} = \mathtt{b}, \mathtt{a} = \mathtt{c}, \mathtt{a} = \mathtt{d}, ...$ where $\mathtt{p} \rightarrow \{\mathtt{b}, \mathtt{c}, \mathtt{d}, ...\}$ at the end of an iteration after points-to information computation and interpretation is done, the contradiction means that $\mathtt{x} \notin (*\mathtt{b} \cup *\mathtt{c} \cup *\mathtt{d} \cup ...)$. This implies, $(\mathtt{x} \notin *\mathtt{b}) \wedge (\mathtt{x} \notin *\mathtt{c}) \wedge (\mathtt{x} \notin *\mathtt{d}) \wedge ....$ This suggests that the pointee $\mathtt{x}$ propagates to the pointer $\mathtt{a}$ via some other constraints, implying that the points-to fact $\mathtt{a} \rightarrow \{\mathtt{x}\}$ is not strictly-realizable by $\mathtt{a} = *\mathtt{p}$, contradicting our hypothesis.

Lemma 1.5: *Decomposing an r-value of* $\mathtt{p}$ *into its prime factors, unmapping the addresses as the primes to the corresponding variables, and mapping the variables to their r-values corresponds to a pointer dereference* $*\mathtt{p}$.

Lemma 1.6: *Load statements are transformed safely.*
Proof: For a $\mathtt{k}$-level dereference $*^{\mathtt{k}}\mathtt{v}$ in a load statement, every '*' adds 1 to the pointer $\mathtt{v}$'s r-value. Thus, for a value $\mathtt{v} + \mathtt{k}$ which we assume to be unique (see *Issues* in Section 2.3), the evaluation involves $\mathtt{k}$ dereferences. Lines 15–24 of Algorithm 3 do exactly this, and by Lemmas 1.3 and 1.5, load statements compute a safe superset.

Theorem 1: *The analysis is safe.*
Proof: From Lemma 1.1—1.6 and Corollary 1.1.

Lemma 2.1: *Address-of statements are transformed precisely.*
Proof: Address of every address-taken variable is represented using a distinct prime value. Further, in Lines 5–9 of Algorithm 1, for every address-of statement $\mathtt{a} = \&\mathtt{b}$, the only primes that $\mathtt{a}$ is multiplied with are the addresses of $\mathtt{b}$s.

Lemma 2.2: *Variable renaming is precise.*
Proof: Since each variable is defined only once and by making use of Lemma 1.3 $\mathtt{a} = (\mathtt{e}_1 \cup \mathtt{e}_2 \cup ... \cup \mathtt{e}_\mathtt{n})$.

Lemma 2.3: *Copy statements are transformed precisely.*
Proof: From Lemma 2.2 and since for a transformed copy statement $\mathtt{a} = \mathtt{a}_{\mathtt{copy}} \times \mathtt{b}$, only the primes computed as the points-to set of $\mathtt{a}$ so far (i.e., $\mathtt{a}_{\mathtt{copy}}$) and those of $\mathtt{b}$ are included. This inclusion is guaranteed to be unique due to the uniqueness

of prime factorization. Thus, a does not point to any spurious variable address.

Lemma 2.4: *Store statements are transformed precisely.*
Proof: For the sake of contradiction, assume that a points-to fact $\mathtt{a} \rightarrow \{\mathtt{x}\}$ is computed spuriously by evaluating a store constraint $\mathtt{a} = *\mathtt{p}$ in Algorithm 1. This means at least one of the following copy constraints computed the fact: $\mathtt{a} = \mathtt{b}, \mathtt{a} = \mathtt{c}, \mathtt{a} = \mathtt{d}, ...$ where $\mathtt{p} \rightarrow \{\mathtt{b}, \mathtt{c}, \mathtt{d}, ...\}$. Thus, at least one of the copy constraints is imprecise. However, Lemma 2.3 falsifies the claim.

Lemma 2.5: *Load statements are transformed precisely.*
Proof: Number of dereferences denoted by $\mathtt{v} + \mathtt{k}$ is the same as that denoted by $*^{\mathtt{k}}\mathtt{v}$. By Lemma 1.5 and 2.3 and by the observation that Algorithm 3 does not include any extra pointee in the final dereference set.

Theorem 2: *The analysis is precise.*
Proof: From Lemma 2.1–2.5.

Theorem 3: *Our analysis computes the same information as an inclusion-based points-to analysis.*
Proof: Immediate from Theorems 1 and 2.
